The dopamine hypothesis of schizophrenia, which was formulated in the **1960s** after the discovery of the antipsychotic actions of chlorpromazine, was extremely successful as a heuristic principle for interpreting aspects of the phenomenology of schizophrenia. The development of improved antipsychotic medications was guided by a search for dopamine blockers based on the concept that schizophrenia is, in part, a hyperdopaminergic state.

The "dopamine hypothesis" of schizophrenia arose from the serendipitous discovery by Jean Delay and Pierre Deniker in **1952** of the antipsychotic effects of chlorpromazine, first developed as a presurgical sedative (Delay et al., 1952).

Dopamine

The dopamine hypothesis of schizophrenia is a model that attributes the positive symptoms of schizophrenia to a disturbed and hyperactive dopaminergic signal transduction. The model draws evidence from the observation that a large number of antipsychotics have dopamine-receptor antagonistic effects. The theory, however, does not posit dopamine overabundance as a complete explanation for schizophrenia. Rather, the overactivation of D2 receptors, specifically, is one effect of the global chemical synaptic dysregulation observed in this disorder.
