¹ Burkitt-like lymphoma with 11q aberration confirmed by needle biopsy of the liver: A case report

Yang HJ *et al.* BLL-11q liver needle

Han-Jin Yang, Zhao-Ming Wang

Abstract

BACKGROUND

¹ Burkitt-like lymphoma with 11q aberration (BLL-11q) is a rare provisional lymphoma, and the majority of cases are usually diagnosed by excisional lymph node biopsy. Here ⁵ we report a case of BLL-11q diagnosed by needle biopsy of the liver in order to improve further understanding of the disease, reduce misdiagnosis, and identify treatment regimens.

CASE SUMMARY

⁷ The patient was a 67-year-old male. He complained of increased frequency of stools for more than one year, periumbilical pain and discomfort exceeding 3 mo. A computed tomography scan suggested an appendiceal malignant tumor with multiple metastases of the peritoneum, omentum, and liver. Needle biopsy of liver nodules ³ showed that the tumor cells were of median size, the shape was consistent, ³ a small number of tumor cells were large, the “starry sky” pattern was evident, and some tissue cells showed multiple apoptotic debris with coarse particles. Immunohistochemistry was ³ positive for CD20, CD10, BCL6, and MYC. The Ki-67 proliferation index was more than 95%. Molecular biological detection indicated a lack of MYC, BCL2 and BCL6 gene rearrangement with 11q aberration. Therefore, the diagnosis was BLL-11q of the liver. After eight courses of chemotherapy, the abdominal and

pelvic peritoneal masses and liver nodules had almost disappeared. The patient recovered well after a follow-up period of more than 13 mo.

CONCLUSION

BLL-11q is rare, but patients treated with standard chemotherapy for Burkitt lymphoma can have a good prognosis. Reducing the dose of chemotherapy or developing specific therapies to prevent overtreatment may be considered, but more case studies are needed.

Yang HJ, Wang ZM. Burkitt-like lymphoma with 11q aberration confirmed by needle biopsy of the liver: A case report. *World J Clin Cases* 2022; In press

Core Tip: Burkitt-like lymphoma with 11q aberration (BLL-11q) is an uncommon lymphoma and is diagnosed by lymph node biopsy. We report a patient with BLL-11q, who presented with predominant digestive tract symptoms. The clinical consideration was colorectal cancer with multiple metastases. The diagnosis was confirmed by needle biopsy of liver nodules, and phagocytosis with a large number of coarse particles was found on pathological morphology, which suggested the diagnosis of BLL-11q. The patient was cured with chemotherapy and recovered well.

INTRODUCTION

Burkitt-like lymphoma with 11q aberration (BLL-11q) was proposed as a provisional subtype in the WHO Classification of Tumors of Hematopoietic and Lymphoid Tissues^[1]. Its morphology and immunophenotype are similar

to burkitt lymphoma (BL). However, it lacks *MYC* gene rearrangement but shows characteristic 11q alterations (11q23.2-23.3 increase and 11q24.1-qter telomere deletion). This tumor is found infrequently, with less than 100 cases reported according to a PubMed search^[2-6]. The demographical and pathological findings in the reported cases are shown in Supplementary Table 1. Only one patient diagnosed by needle biopsy ⁵ of the liver has been reported^[7]. Here, we report a case of BLL-11q diagnosed by liver biopsy.

² CASE PRESENTATION

Chief complaints

The patient was a 67-year-old male. On January 26, 2021, he was hospitalized due to an increase in stool frequency for more than one year, periumbilical pain, and discomfort ² for more than 3 mo.

History of present illness

The frequency of stools increased one year ago without obvious inducement, 4-10 times every day, and a little at a time. He did not have black stool, vomiting, chills or fever. He did not pay attention to his stool frequency and did not see a doctor. Three months ago, he developed periumbilical pain and discomfort without an apparent reason.

² *History of past illness*

The patient had no previous medical history.

Personal and family history

The patient had no family history of genetic diseases and tumors, no history of surgery, and no history of immune deficiency.

Physical examination

On physical examination, his blood pressure was 130/85 mmHg, temperature was 36.8 °C, heart rate was 82 bpm, and respiratory rate was 17 breaths/min. No abnormalities were found in the cardiopulmonary region. No palpable masses were detected in the abdominal region or enlarged lymph nodes in the cervical and inguinal regions.

Laboratory examinations

Routine blood testing showed that leukocytes were $4.25 \times 10^9/L$, erythrocytes were $4.12 \times 10^{12}/L$, platelets were $279 \times 10^9/L$, and lactate dehydrogenase (LDH) was 214 U/L. Blood tumor markers were normal. There were no obvious abnormalities in the bone marrow cytology smear and biopsy. Routine fecal tests and occult blood test were normal.

Imaging examinations

On January 29, 2021, an abdominal computed tomography scan at our hospital showed a mass in the right lower abdomen, suggesting a malignant tumor of the appendix with multiple metastases in the peritoneum, omentum, and liver. The boundary between the mass and the right psoas major muscle was unclear (Figure 1A). On February 3, 2021, B-ultrasound showed a solid hypoechoic mass in the lower segment of the right anterior lobe of the liver, 1.89 cm × 1.61 cm in size, with a clear boundary (Figure 1C). On March 12, 2021, positron emission tomography-computed tomography (PET-CT) showed a soft tissue mass in the liver and right lower abdomen, surrounding the ileocecal junction, with a maximum size of 6.6 cm × 9.4 cm, and a maximum standardized uptake value of 30.3; radioactive uptake in the hepatic capsule margin, abdominal and pelvic mesangium, and omentum was significantly increased (Figure 1D).

A liver nodule biopsy was performed on February 3, 2021. Tumor tissue was diffusely infiltrated. The tumor cells were medium-large, consistent in shape, little cytoplasm, basophilic, with fine granular nuclear chromatin, and occasionally small nucleoli. A few tumor cells were large, with obvious nucleoli and a “starry sky” pattern. There were scattered tissue cells that phagocytized apoptotic debris and nuclear fragments. Multiple (six) apoptotic debris were partially engulfed, with coarse particles. Scattered eosinophils, residual bile ducts, and peripheral degenerative hepatocytes were seen. Immunohistochemical markers CD20, CD10 and BCL6 were positive, MYC (positive, 70%), and the Ki-67 proliferation index > 95% (Figure 2). CD3, BCL2, MUM1, TDT, CD30, CD38, CyclinD1, EBER, and CK (Pan) were negative. Fluorescence in situ hybridization (FISH) detected the *MYC* gene, *BCL2* gene, and *BCL6* gene, counted 200 tumor cells, no red and green signal separated the cells, and the results were negative (Figure 3A-C). FISH analysis of chromosome 11 showed that 11q23 was amplified, and 11q24 was deleted (Figure 3D and F). Antibodies and probe information are shown in Supplementary Table 2.

FINAL DIAGNOSIS

The patient was diagnosed as BLL-11q of the liver.

TREATMENT

The patient received the R-Hyper CVAD part A treatment protocol (Rituximab 700 mg on d0, cyclophosphamide 0.57 g q12 h on d1-3, 13 dexamethasone 40 mg on d1-4 and d11-14, liposome doxorubicin 55 mg on d4, vindesine 4 mg on d4 and d11) d0-d4 chemotherapy, supplemented by stomach protection, anti-nausea, alkalization, and hydration treatment. After three courses of chemotherapy, according to the CT scan, the tumor in the

right lower abdomen had significantly shrunk, and the boundary between the tumor and the right psoas major muscle was obvious (Figure 1B). After six courses of chemotherapy, PET-CT indicated that there was no obvious mass and no abnormally increased fluorodeoxyglucose metabolism in the abdominal, pelvic and peritoneal mesangium. There was also no noticeable increased radioactive uptake in the liver (Figure 1E).

OUTCOME AND FOLLOW-UP

The patient completed eight courses of chemotherapy. He recovered well after a follow-up period of more than 13 mo.

DISCUSSION

Since BLL-11q was named, cases have been reported continuously, but analysis has mainly been based on individual cases or minor cases, and the data on incidence rate and clinical manifestations are very limited. The age at onset of the tumor ranges widely from 2 to 83 years, but it is more common in young patients^[2,8]. In children and adolescents under the age of 18 years, patients with BLL-11q have a median age of 13.9 years, relatively older than those with BL, high-grade B-cell lymphoma (HGBCL) and diffuse large B-cell lymphoma (DLBCL)^[2]. The tumor is found more often in males than in females, and it tends to occur in lymph nodes^[2,3]. In addition to cervical, abdominal, retroperitoneal, and pelvic lymph nodes, tumors in the breast, ileocecum, tonsil, bone, soft tissue, and testis have also been reported. They can invade the liver and pancreas and produce pleural effusions and ascites^[2,7,9,10]. Recently, a case of BLL-11q which originated in the spleen was reported^[11]. The size of the mass differs with the diameter ranging from 2-11 cm^[3]. A tumor greater than 20 cm has also been reported^[6]. Serum LDH may be normal or slightly elevated^[2,6]. Clinical Ann Arbor stages are mostly stage

I/II, and less frequently stage III/IV^[2,3]. The bone marrow and hydrocephalus are rarely involved^[8]. In addition to those with normal immune function, BLL-11q³ in patients with HIV infection, organ transplantation, and immunosuppression have been reported^[10,12-14]. In the present case, the liver, ileocecal, abdominal and pelvic mesangium, and omentum were involved. The International Prognostic Index (IPI) score of group A in clinical stage IV was 4, and was in the high-risk group.

Morphologically, tumor cells mainly grow diffusely, similar to BL, or between BL and DLBCL. They may have a certain degree of cell pleomorphism, and are occasionally nodular^[1,3,8]. Horn *et al*^[5] first proposed that when tissue cells phagocytize 5-9 apoptotic debris and apoptotic fragments with coarser particles, it is speculated that the specificity for 11q abnormality is 91% and the sensitivity is 85%. This has been confirmed by Yu YT and colleagues^[7]. They emphasized that when > 50% of tissue cells engulf apoptotic debris and thicker apoptotic fragments, this can predict 11q abnormalities. Although our case underwent a small liver tissue puncture, this morphological change was also observed, which confirmed its strong diagnostic potential. It is speculated that 11q abnormality may have a specific mechanism to drive the increase in apoptosis frequency, but the specific molecular mechanism requires further confirmation^[5]. Therefore, we believe that when the “starry sky” pattern is obvious, and the tissue cells engulf apoptotic debris and coarse apoptotic fragments, 11q molecular detection should be carried out.

The typical immunophenotype of BL was CD20 +, CD10 +, BCL2 –, and Ki-67 > 90%. There was no significant difference in the expression of CD10, BCL6, MUM1, Ki-67, and MYC proteins between 11q negative and 11q positive cases. However, more 11q positive cases had negative BCL2 than 11q negative cases, and this difference was statistically significant^[11]. It is reported

that flow cytometry is positive for CD16/CD56 and lacks high expression of CD38, which supports the diagnosis of BLL-11q^[6]. No flow cytometry samples were obtained from our case, and the immunohistochemical phenotype was similar to BL, which prompted us to further detect the *MYC* gene. In our case, *MYC*, *BCL2*, and *BCL6* were not translocated, but the increase in 11q23 and the deletion of 11q24 were detected.

BLL-11q is easily confused with some highly invasive B-cell lymphomas. Differential diagnosis: Classic BL: Both morphology and immunophenotype overlap^[1,15], but *MYC* gene rearrangement is present in BL. HGBCL is a double strike or triple strike lymphoma, that is, HGBCL with *MYC* and *BCL2* and/or *BCL6* translocation, and its identification mainly depends on molecular genetic detection. It is described in the literature that a few HGBCLs with positive BL and *MYC* gene translocation can also have an 11q aberration^[9,13]. The diagnosis of BLL-11q requires the lack of *MYC*, *BCL2*, and *BCL6* translocation. DLCBL of germinal center origin: The acquisition or amplification of 11q large fragment can occur, rather than the acquisition of 11q proximal region with deletion of the distal region^[15].

As 11q aberration is not unique to BLL-11q, and other invasive lymphomas such as BL and *MYC* positive or negative HGBCL and DLBCL also exist, the clinical disease spectrum of malignant tumors with 11q aberration is broader than previously assumed^[2,5,9,13]. Whether this lymphoma is a distinct category or a particular variant of other recognized entities is controversial. To improve the understanding of BLL-11q, Gonzalez-Farre *et al*^[16] performed an analysis of copy number alterations and targeted sequencing of a large panel of B-cell lymphoma-related genes in 11 cases. Potential driver mutations were found in 27 genes, particularly involving *BTG2*, *DDX3X*, *ETS1*, *EP300*, and *GNA13*. These results suggest that BLL-11q is a germinal center-derived lymphoma closer to HGBCL or DLBCL than to BL. They think that the term

aggressive B-cell lymphoma with 11q aberration captures their pathological features^[16]. Recently, Kim *et al*^[17] reported a composite lymphoma of BLL-11q and BL. They suggest BLL-11q as a distinct entity from BL. The sequence of molecular detection is to first detect MYC gene rearrangement, and then 11q chromosome detection when MYC gene rearrangement is negative, 11q proximal acquisition and distal deletion are required at the same time^[1,8,9,13]. Only by combining morphology, immunophenotype and molecular biology can the correct diagnosis be made. The most sensitive method reported in the literature is DNA microarray^[8]. Some authors suggest that all MYC rearrangement negative HGBCLs with BL/BL-11q morphology should be detected by microarray or FISH detection with 11q aberration, while others support a step-by-step method, starting with FISH detection. If FISH detection is difficult or negative, then microarray detection is performed^[18].

It has been reported that prognosis of the tumor is good, most are completely resolved after BL standard chemotherapy, Au-Yeung *et al*^[2] reported a two-year event-free survival rate of 100%^[2,3,6,8]. Disease-free survival after 67 mo of follow-up was reported following chemotherapy^[9]. A patient who was suffering from AIDS, after receiving one course of rituximab, cyclophosphamide, pirarubicin, vincristine, and prednisone (R-CTOEP), refused to continue chemotherapy and was followed up for 34 mo, no recurrence or new lesions were found^[12]. The disease course in our case was more than 1 year before diagnosis. The IPI score of group A in clinical phase IV was 4, and was in the high-risk group. He was followed up for more than 13 mo after chemotherapy. The abdominal and pelvic masses and liver nodules disappeared, and the patient is now in a good condition. Therefore, we can consider that BLL-11q is a separate lymphoma subtype^[1,18], and the chemotherapy dose can be reduced, or specific treatment methods can be formulated to prevent overtreatment^[2,18]. However, more case-cohort studies

and clinical comparisons at the same stage and risk are needed to determine the best treatment regimen.

CONCLUSION

BLL-11q can occur in both intra- and extra-lymph nodes. In addition to surgical excision of the specimen, a definite diagnosis can be made when the tissue volume in the needle biopsy specimen is sufficient. In terms of pathomorphology, the tumor cells are of medium size, consistent shape, and the significant “starry sky” phenomenon is accompanied by a large number of phagocytic reactions with coarse particles suggestive of BLL-11q diagnosis. Pathological diagnosis can only be confirmed by immunohistochemistry and molecular detection. Following chemotherapy, patients can achieve satisfactory results, and their prognosis is good. Reducing the dose of chemotherapy or developing specific therapies to prevent overtreatment may be considered, but more case studies are needed.

Figure Legends

Figure 1 Imaging findings. A: On January 29, 2021, ¹²computed tomography (CT) showed multiple space-occupying lesions in the ileocecal bowel, peritoneum and omentum, and the boundary with the right psoas major muscle was unclear (red arrow); B: After 3 courses of chemotherapy, CT showed that the multiple space-occupying lesions in the ileocecal bowel, peritoneum and omentum had significantly shrunk, and the boundary with the right psoas major muscle was obvious (red arrow); C: On February 3, 2021, B-ultrasound showed a solid hypoechoic mass 1.89 cm × 1.61 cm in size with a clear boundary in the lower segment of the right anterior lobe (red arrow); D: On March 12, 2021, ⁸positron emission tomography (PET)-CT

showed a soft tissue mass shadow in the liver and right lower abdomen, surrounding the ileocecal junction, with a maximum standardized uptake value of 30.3. Radioactive uptake in the hepatic capsule margin, abdominal and pelvic mesangium and omentum was significantly increased; E: On September 24, 2021, after 6 courses of chemotherapy, PET-CT showed that there was no obvious mass or increased fluorodeoxyglucose metabolism in the abdominal and pelvic peritoneal mesangium, and no obvious increased radioactive uptake in the liver (white arrow).

Figure 2 Pathological findings. A: Fine needle biopsy of the liver showed liver tissue and tumor tissue (low magnification of HE staining); B: The tumor cells are medium-large, consistent in shape, with a starry sky pattern. Liver tissue found in the left and upper right corners (HE staining 200×magnification); C: Tumor cells have little cytoplasm, with basophilic, fine granular nuclear staining; tissue cells phagocytize apoptotic debris and nuclear fragments; it can be seen that there is multiple apoptotic debris (six) with coarse particles (red arrow) (HE staining 400 × magnification); D: CD20 Labeling of tumor cells was diffuse and strongly positive (Envision method 200 × magnification); E: CD10 labeling of tumor cells was diffuse and strongly positive (Envision method 200 × magnification); F: BCL6 Labeling of tumor cells was diffuse and strongly positive (Envision method 200 × magnification); G: Tumor cells were positive for MYC labeling (70%) (Envision method 200 × magnification); H: Ki-67 proliferation index of tumor cells > 95% (Envision method 200 × magnification).

Figure 3 Fluorescence in situ hybridization detection on gene and chromosomes. A-C: Fluorescence in situ hybridization (FISH) detection on MYC gene (A), BCL2 gene (B), and BCL6 gene (C), all were negative; D:

11q23. 3 was positive, red represents 11q23. 3, and green represents CSP11. 11q23. 3. was amplified (white arrow); E: 11q24. 3 was positive, red represents 11q24. 3 and green represents CSP11. 11q24. 3 was reduced or missing (white arrow).
