## Liver or kidney: Who has the oar in the gluconeogenesis boat and when?

Sahoo B *et al.* Liver and renal gluconeogenesis

Biswajit Sahoo, Medha Srivastava, Arpit Katiyar, Carolyn Ecelbarger, Swasti Tiwari

### INTRODUCTION

<sup>26</sup> Glucose is the primary or even requisite source of energy for many tissues, including the brain, kidney medulla, and red blood cells. Blood glucose levels are maintained within a very narrow range between 3.9-7.1 mmol/Liter. In addition to dietary glucose, glucose produced through the process of glycogenolysis and gluconeogenesis results in the release of additional glucose into the circulation when blood levels drop. <sup>16</sup> Glycogenolysis involves the breakdown of glycogen to glucose-6-phosphate and its subsequent hydrolysis by glucose-6-phosphatase to free glucose. While gluconeogenesis involves the formation of glucose-6-phosphate from non-carbohydrate carbon substrates such as lactate, glycerol, and amino acids with its subsequent hydrolysis by glucose-6-phosphatase to free glucose. <sup>2</sup> The process requires several enzymatic steps and counters the glycolytic breakdown of glucose. The key enzymes in the gluconeogenesis pathway are pyruvate carboxylase (PC), phosphoenolpyruvate carboxykinase (PEPCK, PCK1), fructose 1,6-bisphosphatase (FBP), and glucose 6-phosphatase (G6P)<sup>[4]</sup>. There are three rate-limiting, unidirectional steps in gluconeogenesis, which all occur in the cytosol. The first is the phosphorylation of decarboxylated oxaloacetate to form PEP which is catalyzed by PEPCK<sup>[5]</sup>. The PEP is converted into fructose 1,6-bisphosphate through a series of reactions, which is hydrolyzed to fructose 6-phosphate in the second rate-limiting step via the FBP enzyme. <sup>23</sup> Glucose phosphate isomerase converts fructose 6-phosphate to glucose 6-phosphate. Finally, in the third rate-limiting step, <sup>31</sup> glucose 6-

phosphatase dephosphorylates glucose 6-phosphate to release glucose into the bloodstream (Figure 1).

15

## **GLUCONEOGENESIS IN THE LIVER AND KIDNEYS**

The liver and kidneys are the primary organs that can synthesize glucose through the process of gluconeogenesis, and can also export the synthesized glucose into the bloodstream.

### **WHO USES WHAT?**

Lactate, glycerol, and certain glucogenic amino acids, *e.g.*, alanine and glutamine are the primary substrates accounting for 90% of overall gluconeogenesis<sup>[6,7]</sup>. For liver gluconeogenesis, lactate, which is produced during anaerobic glycolysis, is the primary substrate. In the kidney, glutamine appears to be the major substrate. Although a few studies have suggested lactate as the main substrate, the renal conversion of lactate to glucose was found to be less than that of glutamine (50% *vs* 70% of its overall systemic gluconeogenesis)<sup>[6,8]</sup>. Moreover, in the post-absorptive phase, glutamine contributes 73% toward renal gluconeogenesis, while alanine contributes only 4%. It is the opposite for the liver, where alanine majorly contributes to gluconeogenesis. Moreover, hepatic gluconeogenesis from lactate and alanine is an endergonic process that consumes energy, while renal gluconeogenesis by utilizing glutamine is an exergonic process that produces four ATP/mole of synthesized glucose<sup>[9]</sup>. The transport systems for glucogenic amino acids also vary between the liver and kidneys. In renal tubular cells, glutamine transport depends on the A amino acid transport system, while in hepatocytes the transport depends on the N system. Nevertheless, the differences in glucogenic amino acid substrates would indicate differences in the regulatory mechanisms of glucose production in the two organs.

### **WHO IS MORE SENSITIVE TO HORMONAL REGULATION?**

Insulin, glucagon, and catecholamines regulate plasma glucose levels within minutes through their acute glucoregulatory actions on the liver and kidney gluconeogenesis. While, the effects of growth hormone, thyroid hormone, and cortisol take a long time either by altering the sensitivity of the liver towards the acute-regulatory hormones or by affecting the glycogen stores regulating enzyme activity and gluconeogenic precursor availability<sup>[10]</sup>. Moreover, most of these studies have been done in animals and their effect on renal glucose release in humans is largely unknown.

Insulin is by far the most well-known negative regulator of gluconeogenesis, in both liver and kidneys. Insulin can act by directly activating or deactivating the rate-limiting enzymes for gluconeogenic substrate availability, or by acting on gluconeogenic activators. The <sup>5</sup> insulin-dependent transcriptional control of gluconeogenic gene expression involves the FOXO family of transcription factors which act through the IRS1/Akt2/mTORC1/2 and IRS/PI3k/Akt/FOXO1 pathways<sup>[11-15]</sup>. <sup>7</sup> Recent studies suggest that the kidney may be more sensitive than the liver to hormonal down-regulation of gluconeogenesis<sup>[16]</sup>. Moreover, insulin receptor-specific signaling may be necessary <sup>7</sup> for the down-regulation of renal gluconeogenesis. PT-targeted insulin receptor deletion in mice resulted in an elevation in fasting blood glucose and increased renal protein and mRNA expression of G6P<sup>[17]</sup>. Also, <sup>21</sup> in proximal tubule cell culture, knockdown of the insulin receptor, but not the insulin-like growth factor, type 1 receptor abrogated insulin's inhibitory effects on glucose production<sup>[18]</sup>.

Unlike the liver, where glucagon increases gluconeogenesis<sup>[19]</sup>, the regulation of gluconeogenesis in the kidneys by glucagon is still controversial. Although, upregulation in PEPCK, IRS2, and PGC1 $\alpha$  expression and glucose production by human proximal tubule cells, independent of insulin's action, was observed upon glucagon stimulation<sup>[20]</sup>. Similar gluconeogenic effects of elevated glucagon levels were also reported in type 2 diabetes mellitus (T2DM) subjects<sup>[21]</sup>. Catecholamines also affect glucose release by the two organs, <sup>1</sup> by increasing the availability of gluconeogenic substrates and <sup>5</sup> by decreasing insulin secretion<sup>[22,23]</sup>. In addition, both, glucagon and catecholamines may positively regulate hepatic gluconeogenesis through cyclic AMP-

<sup>34</sup> dependent activation of protein kinase A<sup>[24,25]</sup> and acutely by the <sup>5</sup> phosphorylation of the bifunctional enzyme 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase <sup>2</sup> (PFK2/FBPase-2) at Ser36<sup>[26]</sup>.

### **WHO DRIVES SYSTEMIC GLUCOSE RELEASE DURING STARVATION?**

<sup>8</sup> After overnight fasting, endogenous glucose production is approximately 10-11  $\mu\text{mol/kg/min}$  in humans<sup>[6]</sup>. The liver contributes to systemic glucose production through both, glycogenolysis and gluconeogenesis, while the kidney produces glucose only through renal gluconeogenesis as it does not store glycogen in a healthy state. In the first hour of fasting, hepatic glycogen stores break down to glucose to meet the energy demand. Thus, in the liver, glycogenolysis is considered the primary (approximately 75%) source of <sup>29</sup> glucose production in the early phase of the post-absorptive period while gluconeogenesis contributes approximately 25%<sup>[27]</sup>. It was suggested that only upon the depletion of glycogen stores, hepatic gluconeogenesis take over glucose production. However, other studies reported the contribution of gluconeogenesis at approximately 50% of hepatic glucose production, even in the early post-absorptive period when liver glycogen stores were maximal<sup>[28]</sup>. At the other extreme, Landau *et al*<sup>[29]</sup> reported a 54% contribution of gluconeogenesis after 14 h of fasting, and the percentage rose to 64% after 22 h of fast. Thus, regardless of the length of fasting gluconeogenesis and glycogenolysis in the liver were considered to contribute equally toward glucose production. These assumptions were made as the <sup>13</sup> net organ balance studies suggested the liver as the primary site for glucose production, as <sup>13</sup> kidneys showed little or no net glucose production in healthy humans during starvation<sup>[30-32]</sup>.

<sup>15</sup> A breakthrough in determining the role of kidney gluconeogenesis in whole-body glucose homeostasis came from the studies of Mutel *et al*<sup>[1]</sup> They showed, using liver-specific deletion of the glucose-6-phosphatase gene (L-G6pc/-mice) <sup>3</sup> that the absence of hepatic glucose release had no major effect on the control of fasting plasma glucose concentration. The authors also suggested that, in early fasting, an <sup>19</sup> induction of

gluconeogenesis in the kidneys sustained endogenous glucose production and maintained euglycemia. Re-evaluation of the renal contribution to glucose release during starvation using net renal glucose balance together with a deuterated glucose dilution method suggested that renal glucose production handled approximately 20% of whole-body glucose release<sup>[27]</sup>. In prolonged fasting, renal gluconeogenesis increased and accounted for about 40% of the total systemic gluconeogenesis. Using new methodologies brought to light that the kidneys not only produce glucose in the cortex but also utilize glucose for energy in the medullary region, thus the net organ balance of glucose may not truly reflect renal glucose production. This paradigm-shifting set of studies brought into effect new thinking in that de novo systemic glucose production is likely provided equally by glycogenolysis (in the liver), and gluconeogenesis (approximately 30% by the liver and 20% by the kidney) during periods of extended fasting.

Overall, it has been realized that the percentage contribution of kidneys and livers towards endogenous glucose production changes under various nutritional situations, including long-term fasting. This repartition seems necessary for the body to maintain plasma glucose constant and simultaneously preserve the energetic status of the body for anabolic purposes. However, the predominant mechanism for glucose release into the circulation by the two organs varies in the fed state. In the kidneys, two mechanisms are in operation for the net release of glucose; the high- energy-consuming gluconeogenesis and a relatively lower energy-driven glucose reabsorption process<sup>[15]</sup>. Whereas in the liver, glucose release occurs solely through gluconeogenesis. In the fasting state, however, the inability to reabsorb sufficient glucose, together with inactivated insulin signaling, promotes ATP-consuming gluconeogenesis. The role of the insulin receptor in the fast-fed regulation of gluconeogenesis in the human proximal tubule with insulin receptor substrates as direct effectors has recently been described<sup>[20]</sup>.

## **WHO DRIVES HYPERGLYCEMIA IN DIABETES?**

Increased liver, as well as renal glucose release, have been reported in T2DM<sup>[33-38]</sup>. The liver was commonly believed to be the primary source for this increased release of glucose into the circulation, in humans with T2DM. Although renal glucose release has only been assessed in a handful of studies in humans with T2D, the absolute increase in renal glucose release seems to be comparable to the liver by the combined isotopic-net renal glucose balance technique<sup>[38-40]</sup>. Unlike the liver, where glycogenolysis also contributes to the release of new glucose into the circulation, the increased release of new glucose by the kidney into the circulation is sole, if not exclusively, a result of the rise in gluconeogenesis.

In humans with or without diabetes, renal glucose release into the circulation increased for 2-3 h after a 75-gm oral glucose load, whereas hepatic glucose release was reduced throughout the entire postprandial period<sup>[41]</sup>. However, the average rate of postprandial glucose release was roughly twice as high in diabetic patients as it was in non-diabetic subjects, and renal glucose release accounted for nearly 49% of the overall glucose release. This was predominantly due to defective endogenous glucose release regulation and to a lesser extent, decreased initial ingested glucose splanchnic sequestration. This effect is expected in patients with diabetes having lower postprandial insulin release or insulin resistance<sup>[12]</sup>. "Carryover" of the elevated renal gluconeogenesis observed in the post-absorptive state may have also contributed to endogenous glucose release<sup>[38]</sup>, in addition to the higher availability of free fatty acid (FFA)<sup>[42]</sup>, and gluconeogenic precursors observed in T2DM patients<sup>[43]</sup>. Nevertheless, increased gluconeogenesis (both liver and kidneys) contributes to hyperglycemia in T2DM. However, in the kidneys enhanced glucose reabsorption, *via* sodium-glucose cotransporters (SGLT1 and SGLT2) may also sustain hyperglycemia in T2DM. Inhibiting SGLT2 Lowers blood glucose levels in T2DM<sup>[44]</sup>. Although, two distinct mechanisms have been indicated to improve glycemic control and reduce the plasma glucose levels by SGLT2 inhibitors; first, by increasing the removal of plasma glucose and second, by ameliorating glucotoxicity, which leads to improved insulin sensitivity in peripheral tissues and enhanced  $\beta$  cell function<sup>[45]</sup>. Paradoxically, SGLT2 inhibitors

also increased the hepatic gluconeogenic response while decreasing plasma insulin, and offset by approximately 50% the increase in urinary glucose excretion<sup>[45-47]</sup>. The increase in endogenous glucose production by SGLT2 inhibitors corroborated well with the observed increase in plasma glucagon concentration<sup>[46]</sup>. Glucagon is a powerful stimulator of hepatic gluconeogenesis as already discussed in the previous section. Glucosuria-induced glucagon secretion by SGLT2 inhibitors is beyond the scope of this review, however, glucosuria through neural reflex might activate the kidney-liver axis directly or through neuronal centers in the CNS<sup>[45]</sup>. Nevertheless, there are studies to suggest SGLT2 inhibitors might enhance gluconeogenesis predominantly in the kidney<sup>[46,48]</sup>. Moreover, However, the influence of diet intake control on the metabolic effects of SGLT2 inhibitors, including gluconeogenesis has been observed<sup>[49]</sup>.

The increase in gluconeogenesis in diabetes has been attributed to impaired insulin suppression of PEPCK, and other gluconeogenic enzyme activities<sup>[33,50-52]</sup>. Elevated gluconeogenic gene expression in the kidneys was reported in proximal tubules-specific IRS1/2 double-knockout (KO) mice. These mice also exhibited attenuated phosphorylation of insulin signaling molecules including, Akt and FOXO1<sup>[15]</sup>. Similarly, proximal tubule-specific IR KO increased fasting glucose concentration and renal G6Pase mRNA in KO mice<sup>[17]</sup>. Moreover, studies conducted in a rat model of T2DM<sup>[53]</sup> and T2DM patients<sup>[54]</sup> also demonstrated the downregulation of IR subunit protein levels, the activation of glycogen synthase kinase 3 beta kinase, and increased gluconeogenic enzymes in proximal tubules.

Another mechanism by which insulin resistance can enhance gluconeogenesis is through impaired insulin-induced suppression of lipolysis. Accelerated lipolysis in insulin resistance or insulin deficiency releases FFA and glycerol into the circulation, demonstrating a role for adipose tissue as another source of increased substrate supply for gluconeogenesis<sup>[6,55]</sup>. The rates of glycerol turnover and gluconeogenesis from glycerol are seen to increase in overnight fasted T2DM patients<sup>[56,57]</sup>. In renal tissues of human diabetes patients, an increase in plasma concentrations of alanine, glycerol, and lactate was detected demonstrating the role of increasing substrate availability enabling

the possibility of enhanced gluconeogenesis<sup>[58,59]</sup>. In diabetic rats, the elevated renal NADPH oxidase activity and oxidative stress were suggested to upregulate PEPCK expression *via* CREB and the ERK1/2 pathway leading to accelerated renal gluconeogenesis<sup>[50,60]</sup>.

Unlike diabetes, where gluconeogenesis gets regulated in both the liver and kidney, in metabolic acidosis, such as occurs in type 2 diabetes, regulation is primarily in the kidneys<sup>[61,62]</sup>. To counterbalance acidosis, the kidney generates ammonia, mainly from glutamine deamination, which forms  $\alpha$ -ketoglutarate ( $\alpha$ -KG) and  $\text{NH}_4^+$  *via* the ammonia genesis pathway<sup>[63]</sup>. The proximal tubule imports glutamine and catalyzes it into glutamate, freeing up  $\text{NH}_4^+$  to secrete into the lumen to eliminate acid equivalents, and reabsorbs basolaterally bicarbonate to normalize blood pH. Glutamate in the PT is then converted to  $\alpha$ -ketoglutarate, which is a substrate for gluconeogenesis<sup>[64]</sup>. It is the transcription of the PEPCK-C gene in the kidney cortex by metabolic acidosis which is unique to the kidney, whereas the transcription of PEPCK-C in the liver does not respond to changes in Ph<sup>[65]</sup>.

## REPARTITIONING ENDOGENOUS GLUCOSE PRODUCTION AMONG ABLE ORGANS

Inter-organ coordination among the liver, kidneys, and potentially intestine may be expected if glucose and energy homeostasis is to be maintained<sup>[1]</sup>. A similar regulation may be expected during the anhepatic phase of liver transplantation in humans. In mice with liver-specific deletion of the glucose-6-phosphatase gene, the absence of hepatic glucose production, glucagon was suggested to account for the basal induction of the renal glucose-6-phosphatase gene<sup>[1]</sup>. Moreover, glucose production was suggested to counter-regulate insulin-induced hypoglycemia in humans during increased glucagon and cortisol secretions<sup>[66]</sup>. These studies highlight the important role of the kidney in endogenous glucose production. The similar, the liver is also expected to compensate for hypoglycemia due to renal insufficiencies, however, it does not appear to be the case always as patients with renal failure are prone to hypoglycemia<sup>[67,68]</sup>. Although,

underlying hepatic issues in such patients could be a possibility where in individuals with reduced hepatic glycogen stores or less available gluconeogenic substrates<sup>[69]</sup>.<sup>17</sup> Moreover, acidosis would limit the ability of the liver to compensate *via* hepatorenal reciprocity<sup>[70]</sup>. In this vein, renal gluconeogenesis diminution was shown to promote the repartition of endogenous glucose production in intestinal gluconeogenesis leading to the sparing of glycogen stores in the liver in mice lacking kidney-specific glucose-6-phosphatase gene<sup>[71]</sup>. Thus intestine-liver crosstalk might take place in the situations of deficient renal glucose production, such as chronic kidney disease (CKD). However, studies are warranted to determine the contribution of intestinal gluconeogenesis to systemic glucose release and to confirm that the repartition of endogenous glucose production takes place and contributes to a glycemic reduction in CKD with reduced renal gluconeogenesis. More studies are needed to understand the relative role of the liver vis-à-vis extrahepatic gluconeogenic organs in glucose homeostasis are needed.

## CONCLUSION

Gluconeogenesis in the liver as well as kidneys is now considered important in maintaining glucose homeostasis. The difference in the preference for gluconeogenic substrates by the liver and kidneys, and the hormonal regulation of the process in the two organs, would imply that the regulatory mechanisms of glucose production are not the same in the two organs. Moreover, the contribution of kidney *vs* liver gluconeogenesis may vary under certain physiological and pathological conditions. For example, in the early phase of fasting, as the hepatic glycogen gets depleted, the systemic glucose production was considered equally by glycogenolysis (in the liver), and gluconeogenesis (approximately 30% by the liver and 20% by renal gluconeogenesis). While in prolonged fasting, renal gluconeogenesis increases and accounts for about 40% of the total systemic gluconeogenesis. In the pathological state of T2DM, increased gluconeogenesis in both, the liver and kidneys, contribute towards hyperglycemia. While in metabolic acidosis, which sets in response to diabetes, gluconeogenesis induction exclusively occurs in the kidneys, and liver gluconeogenesis

remained unaffected. Similarly, differential effects of SGLT2 inhibitors on renal and liver gluconeogenesis have been reported in the liver and kidneys. Besides, the two organs can compensate, at least partially, for the impaired glucose release due to renal or liver insufficiency suggesting an inter-organ coordination to maintain glucose and energy homeostasis. For translational implication, more studies in the area are needed to know the real driver of systemic glucose production under pathological states, such as in patients with liver or renal insufficiency.
