Spectrum of COVID-19 induced liver injury- a review report

Lokjan Singh, Anil Kumar, Maya Rai, Bibek Basnet, N Rai, Pukar Khanal, Kok-Song Lai, Wan-Hee Cheng, Ahmed Morad Asaad, Shamshul Ansari

Abstract

The coronavirus disease-19 pandemic has caused changes in the global health system, causing significant setbacks in healthcare systems worldwide. This pandemic has also shown resilience, flexibility, and creativity in reacting to the tragedy. The Severe-Acute-Respiratory-Syndrome-Corona Virus Disease-2 infection targets most of the respiratory tract, resulting in a severe sickness called acute respiratory distress syndrome that may be fatal in some individuals. Although the lung is the primary organ targeted by COVID-19 viruses, the clinical aspect of the disease is varied and ranges from asymptomatic to respiratory failure. However, due to an unorganised immune response and several affected mechanisms, the liver may also experience liver cell injury, ischemic liver dysfunction, and drug-induced liver injury, which can result in respiratory failure because of the immune system's disordered response and other compromised processes that can end in multisystem organ failure. Patients with liver cirrhosis or those who have impaired immune systems may be more likely than other groups to experience worse results from the SARS-CoV-2 infection. We thus intend to examine the pathogenesis, current therapy, and consequences of liver damage concerning COVID-19.

INTRODUCTION

The continuing infection caused by coronaviruses, which exploded in 2019, has accelerated into a pandemic problem worldwide. The disease is mainly a respiratory tract viral infection caused by newly emerging strains of coronaviruses. More than 60 million confirmed COVID-19 cases, including almost 1.5 million deaths, have been reported globally in 189 countries since its inception up to October 2022 [1]. SARS-CoV-2 disease infection has mainly targeted the respiratory tract system. It can cause severe disease with acute respiratory distress syndrome, which seems to increase its potential fatality in some infected patients [2]. However, lately, the notion that COVID-19 is a systemic infection and inflammatory disease is gaining eye-catching attention, as the disease is showing a systemic feature that affects other visceral organs, including the liver and gastrointestinal tract [3-7]. The chief viral receptor for SARS-CoV-2 infection is angiotensin-converting enzyme 2 [8, 9]. After virus attachment to the host cell, the host transmembrane serine protease-2 (TMPRSS2) primes the viral S protein [10]. The viral RNA forms two major polyproteins in the host cytosol: protein phosphatase 1 and protein phosphatase 1 ab, which is further converted into 16 non-structural proteins (nsp1 to nsp16) [11]. Phosphatase 1 ¹⁴ unlike SARS-CoV-2 infection-induced lung system and myocardial injury, the clinical manifestation of liver organ involvement has been a point of contention since the beginning of the COVID-19 pandemic [3, 12, 13-18]. The debate includes potential path physiology mechanisms where actively viral replication of SARS-CoV-2 in the liver produces liver cytotoxicity and drug-induced liver injury, exacerbating underlying liver disease [19, 20]. The incidence of increased concentration of liver transaminase enzymes Aspartate aminotransferase and Alanine aminotransferase in COVID-19 patients ranged from 2.5% to 76.3% [21-24]. As the liver is humans' primary metabolic and detoxifying organ, the therapeutic efficacy and safety profile could alter the moderate loss of hepatic function. As such, mechanistic insights causing liver injury linked to COVID-19 are required. So far, there is only little comprehensive evidence of underlying histopathological changes. In addition to vascular abnormalities that include liver cell necrosis, mild lobular and portal inflammation, unbalanced portal vein branches producing intrahepatic, typically ductular proliferation, and hepatic steatosis

(microvesicular) seem to be regularly observed in the livers of diseased patients^[25,26-29]. Although through rRT-PCR, viral RNA has been detected in the liver among major organs excluding the respiratory tract^[13], although a classic hepatic picture has not been reported yet, hepatic tropism, direct cytopathic effects are the potential mechanisms for infections associated with liver injury^[19, 26-29]. S protein is the principal mediator for the entrance of SARS-CoV-2, which interconnects with the host ACE2 receptor and TMPRSS2 receptors specifically^[30]. However, other factors, such as ganglioside (GM1)^[31], could affect how S protein and ACE2 interact. Recently, Ou and colleagues evaluated the capacity of S protein-containing pseudovirions to infect several cell lines. Interestingly, viral vectors encoding the S protein were more effective at transfecting the HuH7 hepatocyte cell line and the Calu3 human lung cancer cell line than the control pseudovirions^[32]. As permissive cell types for coronavirus infection are recognised, hepatocyte cell lines like HuH7 cells have emerged as viable positive controls in SARS-CoV-2 immunostainings^[33]. These findings imply that SARS-CoV-2 infection of human liver ductal teratoma may be possible. Viral replication may occur inside the bile duct epithelium despite the discovery of noticeably greater ACE2; no direct proof of SARS-CoV-2 cholangiocellular infection has yet been revealed in infective patients with COVID-19. For the detection and identification of SARS-CoV-2 viral RNA or proteins in bile, which is largely generated by hepatocytes and cholangiocytes, is an indirect indication of SARS-CoV-2 cholangiocellular infection and ongoing direct interaction between biliary fluids with cholangiocellular apical membrane. However, only a single case report indicates SARS-CoV-2 RNA is present in bile^[34]. Activating hepatic stellate cells is crucial as the primary source of cellular fibrosis in developing chronic liver disorders^[35]. Hepatocellular and cholangiocellular damage caused directly or indirectly by COVID-19 may produce a proinflammatory milieu that leads to the activation of hepatic stellate cells and, as a result, the development of fibrosis. Fibrosis has been reported in patients with non-alcoholic fatty liver disease or underlying chronic liver disease. Long-term follow-up studies are required to establish hepatic fibrosis as a potential long-term side effect of COVID-19, especially in patients with pre-existing

liver illnesses, even though the current evidence suggests minor and transient liver damage associated with the virus. SARS-CoV-2 can cause cytopathic consequences such as host lipid metabolism and mitochondrial dysfunction. Hepatic steatosis in patients may be caused by cytokine storm-induced immunopathology, activity, and adverse medication reactions such as corticosteroids. Microvesicular steatosis is often brought on by abnormalities in mitochondrial oxidation, either hereditary or acquired; mammalian target rapamycin (mTOR), which serves as the primary regulator for autophagy, also stimulates de novo lipogenesis [36-40]. Through mechanisms reliant on the viral (non-structural protein 6/nsp6), which is substantially husbanded in SARS-CoV-2 and has been demonstrated in hijacking the autophagy pathway [41-43]. Additionally, it has been discovered that cells infected with Middle East Respiratory Syndrome, HuH7, exhibit hyper-activation of the mTOR pathway, which prevents viral replication when inhibited by the drug rapamycin [44]. Given the most recent findings that SARS-CoV-2 infection limits autophagy [45], it is probable that the mTOR-dependent infection mechanisms of SARS-CoV-2, SARS-CoV, and MERS-CoV are related. Furthermore, it has been demonstrated that IL-6 stimulation dramatically boosts mTOR activity [46]. The most common factor in COVID-19-associated ARDS is the need for invasive ventilation, substantial doses of positive end-expiratory pressure, and vasoconstrictor therapy due to hemodynamic instability [47-50].

MECHANISM OF SARS-COV-2 INFECTION

The immune mechanism of pathogenicity is shown in Figure 1. The entry of the SARS-CoV-2 virus into the host cells requires dense glycosylated spike protein containing two functional components, S1 and S2. The S2 subunit controls the fusion of the viral and cell membranes, whereas the S1 subunit controls the virus's binding to the host cell receptors [51]. The serine protease TMPRSS2 must first initiate the S protein. TMPRSS2 breaks down the S protein at the S1/S2 and S2 subunit sites [8]. The receptor-binding domain (RBD), comprised of around 300 amino acids, is a trimer of separate monomers that make up the S protein, which has a length of roughly 1300 amino acids. The RBD

on S protein plays a specific role that involves direct participation when host receptors are recognised [53, 54, 55]. Zhou *et al* showed that S protein and ACE2 binding are necessary for infection in HeLa cells [9]. Walls and associates also discovered the activity of human ACE2 as a SARS-CoV-2 functional receptor [57]. In a metaphor, the virus S protein can unlock the human body's ACE2 Lock. The SARS-CoV-2 S protein has 10–20 times the affinity of ACE2 compared to SARS-CoV, as reported by surface plasma resonance analysis [53]. This is a significant finding that could help explain the virus's high infectivity rate. Many studies have reported the activity of human ACE2 as a SARS-CoV-2 functional receptor [57–58].

HEPATOPATHY/RISK FACTOR

There is insufficient data regarding the influence of Hepatitis B on COVID-19, which has a high incidence, particularly in Asia and China. As per the studies, 2% of severe COVID-19 cases involved Hepatitis B infection compared to mild COVID-19 cases (0.06%) [59]. Patients who have a history of hepatitis B or C infection are more likely to develop severe hepatitis, similar to the higher susceptibility for developing severe immunodeficiency infection faced by patients with cirrhosis [3, 60–62]. In comparison to others, liver-diseased patients develop leukopenia and lymphocytosis more commonly, as they suffer from conditions like leukocytosis with neutrophilia and elevated C-reactive protein [63]. People with related gastrointestinal neoplasms express a higher degree of angiotensin-2 receptors, contributing to a precarious risk of SARS-CoV-2 infection since the enzyme has been shown to provide an entry for the virus to enter the cells. However, this could be regulated by the systemic inflammatory responses and gastrointestinal tract level, as angiotensin 2 modulates this response [64]. Monocyte-1 chemo-attracting protein (MCP-1), known to aggravate COVID-19 and promote steatohepatitis, was higher in the serum of coronavirus-infected patients. [18].

ETIOLOGY OF LIVER INJURY IN COVID-19-INFECTED PATIENTS

¹
Viral immunologic injury: SARS-CoV-2 has also been successfully detected in blood and fecal samples from COVID-19 patients, indicating potential intestinal involvement of the virus [66–68]. Through tests with HeLa cells that produced ACE2, Zhou *et al* demonstrated that ACE2 is the cell receptor for the entrance of SARS-CoV-2 into host cells [9]. It was recently found that cholangiocytes might express ACE2 at a level up to 20 times greater than hepatocytes. SARS-CoV-2 may be able to infect cholangiocytes and lead to bile duct dysfunction, as per the expression pattern of ACE2 (Figure 2). Viral immunologic damage may be one of the causes of liver injury since cholangiocytes are involved in immune responses and liver regeneration on a multifaceted and crucial level. In individuals with COVID-19, levels of ALP and GGT, which indicate bile duct damage, do not significantly rise despite the clinical data showing and demonstrating elevated levels of AST, ALT, and LDH in these individuals. Additionally, the autopsy report revealed no viral inclusions in the liver tissue^[70].

Damage of cholangiocyte by SARS-CoV-2

According to research by Qi *et al*, the epithelial cells of the bile duct express the ACE2 receptor 20 times more than liver cells [71, 72]. It implies that SARS-CoV-2 may damage and infect bile duct cells directly, which could eventually result in bile duct dysfunction (Figure 2). Epithelial cells for bile ducts are crucial for liver regeneration and the immune system; thus, liver damage may result when SARS-CoV-2 infects them and results in cholestasis [71, 72]. Increased concentrations of ALP and GGT are reliable signs of damage to bile duct epithelial cells [73]. More studies are necessary to firmly connect liver damage to the bile duct cell damage brought on by the SARS-CoV-2 infection. Researchers have hypothesised a potential mechanism for SARS-CoV-2-induced liver damage. Infection of liver cells occurs when hepatic parenchymal cells, which are produced from bile duct epithelial cells, compensate for the hyperplasia of ACE2 expression in the liver tissues [74]. Unspecific liver inflammation can cause an increase in cytokines and inflammatory biomarkers, including ILs-2, 6, 7, and 10, interferon-gamma inducible protein 10, and tumor necrosis factor (TNF) alpha [12, 76], which can cause

6
severe damage (such as hepatomegaly, elevated serum transaminase, hyper bilirubin, hepatic encephalopathy, and even liver failure). In case inflammatory response syndrome worsens without appropriate management, COVID-19 patients may experience multiple organ failures and death [12, 77].

Hypoxic injury

The liver is susceptible to cardiovascular abnormalities because of composite vascular supply and substantial metabolic activity. The condition known as ischemic hepatitis, known as hypoxic hepatitis, is frequently found in critically ill patients and is a consequence of underlying circulatory, cardiac, or respiratory failure that can result in passive congestion or reduced hepatic perfusion [78, 79]. Systemic stress causes a compensatory reduction in peripheral and splanchnic blood flow, which, in turn, causes a reduction in hepatic blood flow and, as a result, hepatocellular hypoxia, particularly in zone 3 [12, 80]. Cell injury via lipid peroxidation can occur when reactive oxygen species are generated by re-exposing ischemic hepatocytes to oxygen in a condition called reperfusion injury [81]. Furthermore, Kupffer cells could trigger the reunion and activation of polymorphonuclear leukocytes by producing cytokines as a response to ischemia [81].

Drug-induced damage to the liver

In the interim, a variety of different medications including antiviral (lopinavir /ritonavir, remdesivir), antibiotic (macrolides), antimalarial/antirheumatic (hydroxychloroquine), immunomodulating (tocilizumab, corticosteroids), and antipyretic (acetaminophen) medications, are being practised in clinical studies or an off-label manner. However, most medications (such as ritonavir and remdesivir) have already shown hepatotoxic potential (Figure 2). Also included is corticosteroid treatment, which the World Health Organisation now advises for patients having severe SARS-CoV-2 infections [82]. These findings are further supported by the Human Protein Atlas database, which demonstrates that the greatest pattern of ACE2

expression throughout the whole human intestinal cells have a variety of cell types (information accessible at <https://www.proteinatlas.org/ENSG00000130234-ACE2/tissue>). Additionally, it has been proven that human intestine organoids are susceptible to SARS-CoV and SARS-CoV-2 infections [83]. The most common clinical symptoms, including fever, coughing, exhaustion, and shortness of breath, were highlighted in early clinical trials. Later investigations were able to unearth evidence that COVID-19 also had extrapulmonary manifestations. Since the liver is the primary organ for metabolism and detoxification, it is essential to maintain optimal liver function when utilising any of the COVID-19 therapeutic modalities. It is well known that liver damage results from hepatic inflammation, including activation of innate immune cells and cytokine production [84]. An old drug called chloroquine has recently been tested in treatments of COVID-19 patients after showing indications of being a potential treatment. The drug's superior efficacy in viral control was well demonstrated when concurrent clinical trials on chloroquine conducted at ten hospitals across China showed successful inhibition of viral replication [85]. The pharmacodynamics of this drug in treating COVID-19 may show the involvement of the arresting of cytokine storms, the activation of CD8T cells or the prevention against endocytosis-mediated uptake of the virus [86]. The COVID-19 virus primarily affects the lungs [77]. However, it can also harm the liver through a variety of mechanisms, including an unorganised immune response, virus-related liver cell damage, Drug-Induced Liver Injury (DILI), and ischemic liver dysfunction in the context of multi-organ failure [88]. Patients with cirrhosis and those with impaired immune systems may be more likely to experience negative consequences after contracting SARS-CoV-2 [21]. The direct cytopathic impact of COVID-19, DILI, an uncontrolled immunological response, or sepsis are only a few of the possible causes of liver damage [90]. In COVID-19 patients who also experienced diarrhea, SARS-CoV-2 ribonucleic acid was found in blood and stool samples, indicating that the liver is likely implicated in the illness's etiology [68]. The underlying condition might become worse because of COVID-19. Chronic liver disease (CLD) increases the risk of death, especially in critically ill patients, by causing hepatic

decompensation or acute-on-chronic liver failure [57,90, 92]. In severe COVID-19 infections, liver damage is more frequently caused by an inflammatory cytokine storm [90, 95] than by the virus itself in a direct cytotoxic manner [90]. While in the final stage of SARS, the continued interaction between the lung and systemic inflammation causes multi-organ vascular dysfunction and a cytokine storm, and pro-thrombotic factors aggregate and produce thrombosis due to the bone marrow and liver acute phase responses [96]. The human body's primary organ for drug metabolism is the liver. The medications used to treat COVID-19 individuals may harm the liver. According to Kulkarni *et al*, there is drug-induced liver damage as frequently as 25.4% of the time [21]. In the US, antimalarial drugs, including chloroquine and hydroxychloroquine, have received emergency authorisation to treat COVID-19. However, because hydroxychloroquine is well known to concentrate in the liver, individuals with hepatitis or other hepatic illnesses, as well as those taking other medications known to be hepatotoxic, should exercise caution [98]. Along with antimalarial drugs, antiviral drugs such as lopinavir-ritonavir, remdesivir, and favipiravir have been utilised to treat COVID-19. According to one case study, remdesivir was the drug that produced the most instances of hepatotoxicity, with 23% of patients reporting elevated levels of liver enzymes linked to the drug [99]. A 50-year-old man who developed Acute Respiratory Distress Syndrome (ARDS) and died from severe COVID-19 had his first COVID-19-related autopsy. The liver's autopsy revealed minor lobular and portal activity, as well as moderate microvesicular steatosis. The SARS-CoV-2 virus or liver damage brought on by drugs is thought to be the source of the injury. There was an increase in proinflammatory CCR6+Th17 in CD4 T cells and cytotoxic granulations in CD8 cells. Hepatocyte dysfunction may also be caused by decreased CD4 and CD8 cell numbers [100]. The clinical findings of patients with and without a history of non-alcoholic fatty liver disease (NAFLD) were compared. The results showed that patients with NAFLD had a longer viral shedding time (p 0.0001) and a greater probability of disease development. According to the research published by Sonzogni and associates [101], a hepatic biopsy from one of these patients revealed microvesicular steatosis along with over-activation

of T cells, which raised the potential for the collateral damage of the liver caused by virally-induced cytotoxic T-cells. The main finding of a study reveals that patients with severe and non-severe COVID-19 may be at combined risk for elevated blood alanine aminotransferase (ALT) levels. In adult patients with severe and non-severe COVID-19, the secondary outcomes included the risk of the variant parameters viz., elevated AST, hyperbilirubinemia and hypoalbuminemia. The amount of GGT from the included prior studies was also evaluated using a pooled mean difference (MD). Serum ALT or AST values over 40 U/L were deemed to be high. As opposed to hypoalbuminemia, defined as a serum albumin level below 40 g/L, hyperbilirubinemia is defined as a total bilirubin level greater than 17 mmol/L [102]. Immune-mediated injury, or ischemic hepatitis, can result from a significant systemic inflammatory response brought on by COVID-19. Current therapies include lopinavir/ritonavir, hydroxychloroquine, and remdesivir, all of which have the potential to be hepatotoxic and increase the risk of liver damage (DILI) [103]. The underlying chronic hepatitis B may reactivate while using tocilizumab or other immunosuppressive options. Although it has been hypothesised that viral replication within the infected hepatocytes might directly induce cytotoxicity, SARS-CoV-2 viral inclusions have not been found in the liver [70]. The clinical signs and symptoms of COVID-19 might be anything from asymptomatic to respiratory failure. Fever (50%) and cough (38%) are the symptoms that patients experience the most frequently. Patients have also mentioned experiencing other symptoms such as headaches, nausea, vomiting, and diarrhea [105, 106]. Inflammatory cytokines, including IL1, IL6, IL8, and TNF-alpha, increase COVID-19 severity. When there is a serious infection, abnormal liver enzyme and bilirubin levels are discovered, which makes it challenging to treat individuals with liver disease who are also on immunosuppressants, notably cirrhosis or autoimmune hepatitis [107, 108, 109]. Conversely, investigations have indicated a relation between elevated lactate dehydrogenase levels, creatinine kinase, and myoglobin in critically ill COVID-19-infected patients. Therefore, it is proposed that elevations of aminotransferase levels might also be due to other conditions apart from liver damage. Nevertheless, COVID-19 infection could cause

myositis similar to that caused by severe flu. A liver biopsy of a patient who died due to COVID-19 infection revealed the presence of microvesicular steatosis as well as mild lobular and portal inflammation [17, 111]. Purely hepatocellular and Cholestatic types of drug-induced liver damage are clinical conditions. Patients with COVID-19 who have abnormal liver function are typically described as having hepatocellular damage. The primary signs and symptoms of COVID-19 are fever, cough, exhaustion, and dyspnea. Because acetaminophen is a common constituent in antipyretic medications, some COVID-19 patients may have a history of using them. These substances are known to be typical medications that can directly poison hepatocytes. The use of several patented Chinese medications to prevent COVID-19 infection may potentially induce liver damage. Recent liver pathology findings from analysing COVID-19 patients point to the possibility of drug-induced liver damage, as the data revealed the presence of mild lobular inflammation and moderate microvascular steatosis [104]. Antiviral medications like ribavirin, in addition to altering liver function, may also induce or worsen tissue hypoxia through hemolysis, which might raise blood liver enzyme levels. Before receiving COVID-19 medication, patients with chronic liver diseases like hepatitis B or C may already have increased transaminase levels, which might increase their chance of developing drug-induced liver damage. As a result, individuals with COVID-19 who also have basic liver disorders as comorbidities are clinically treated with antipyretic medications, traditional herbal remedies, or antiviral medications. Multiple proinflammatory cytokines and inflammatory indicators, including TNF, interleukins viz. ILs-2,-6,-7,-18, granulocyte-colony stimulating factor, interferon, and ferritin, can be abundantly released when a cytokine storm occurs [12]. Fulminant and deadly hypercytokinemia may start a series of events that result in tissue damage or organ failure, including liver failure [113].

Autoimmune liver disease

The clinical effect of pre-existing immunosuppression on the severity of COVID-19 is still an intricate topic. The hazards that some illness groups confront are a source of worry. For instance, individuals with rheumatoid diseases and inflammatory bowel

diseases, respectively, have been linked to greater disease severity while using maintenance corticosteroids and thiopurines [114, 115]. However, the effect of immunosuppression on the course of the illness in patients who have had solid organ transplantation (SOT), such as liver transplantation (LT), resembles that of non-immunosuppressed persons (described below) [116, 117]. Additionally, interval meta-analyses confirmed that immunosuppressed individuals do not have a noticeably higher chance of contracting severe SARS-CoV-2 infections [118, 119]. SARS-CoV-2 is a member of the same family as SARS-CoV and MERS-CoV, the Coronaviridae. They are pathogenic and have a similar structure to the genomic sequence of SARS-CoV-2, which is 80% and 50% identical to that of SARS-CoV and MERS-CoV, respectively [51]. One week after the start of the illness, the presence of severe symptoms, including dyspnea and hypoxemia, might be a marker of severe pneumonia, which can result in Acute Respiratory Distress Syndrome (ARDS), multiple organ dysfunction syndromes (MODS), and even mortality [125]. Due to its similar genetic lineage B, the new coronavirus reacts to the same receptor as both beta-coronaviruses [126]. The (RBD), a ligand that interacts with the host cell surface receptor, is present in the glycoprotein (S protein) located on the virion envelope spike, allowing for the fusing of membranes, viral penetration, and viral multiplication [126,127]. Although the target receptor is mainly expressed in type II Pneumocyte of the lungs, the predominance of extrapulmonary symptoms suggests that SARS-CoV-2 infection may potentially impact other organs. It has been established by transcriptomics and immunohistochemical investigations that the lower respiratory tract, heart, lungs, ileum, oesophagus, kidney, and bladder contain the largest percentage (>1%) of ACE2 receptors. Other organs, such as the liver, stomach, brain, pancreas, arteries, endothelium, breast, uterus, oral and nasal mucosa, and ovary, have lower ACE2 expression [128]. The majority of SARS-CoV-2 infection risk factors are associated with metabolic syndrome. As a vital organ for lipid metabolism, the liver is a critical factor in determining metabolic disorders and glucose metabolism. As a result, several studies related severe COVID-19 to Metabolic Dysfunction-Associated Fatty Liver Disease (MAFLD) [12]. Even when compared to the

meta-analysis statistics described before ^[28], patients with underlying hepatic problems were older and afflicted with numerous additional comorbidities, like hypertension (68%) or diabetes (48%). The previously mentioned SARS-CoV-2 target receptor has a variable distribution in the liver. Several published reviews have determined its presence in cholangiocytes and lack in Kupffer or sinusoidal endothelial cells ^[131, 132]. It has been discovered that, among those over 65, gender has no bearing on the likelihood of this complication ^[133, 134]. The connection between low testosterone and clinical outcomes, likewise fatty liver and atherosclerosis, metabolic syndrome, type 2 diabetes, and obesity, is one hypothesis that has been proposed. Female sex hormones have a preventive effect against these diseases in younger women ^[135]. Individuals with chronic hepatitis C, alcoholic liver cirrhosis, alcoholic liver damage, and chronic hepatitis B were shown to have the lowest association. In contrast, those with non-alcoholic liver disease and non-alcoholic cirrhosis had the strongest association. Additionally, SARS-CoV-2-infected individuals who also had pre-existing liver illnesses showed greater hospitalisation and mortality rates than other patient groups ^[136]. Age, having non-liver cancer, and having higher baseline blood creatinine levels are all risk factors for patient mortality ^[137]. Immunosuppressants used to lower transplant rejection risk may make patients more susceptible to COVID-19, but they may also reduce the uncontrolled inflammatory response that results from SARS-CoV-2 infection. Additionally, long-term immunosuppressant usage may lengthen the viral shedding period, extending the duration of the communicable period ^[138]. For patients with acute liver failure (ALF/ACLF), a high MELD score, or hepatocellular carcinoma (HCC) at the Milan criteria's top limits, most societies advise against transplantation. Both organ donors and receivers should be checked for SARS-CoV-2 infection as an additional precaution ^[139]. SARS-CoV-2 vaccines are being developed at an unprecedented rate. Since the start of the pandemic, 126 new vaccines have been put into clinical development, as per the WHO COVID-19 vaccine tracer. WHO has given the go-ahead for seven of them for commercial usage. BNT162b2 (Pfizer-BioNTech) and mRNA-1273 (Moderna), based on the mRNA encoding SARS-CoV-2 spiny glycoprotein variations,

are the most widely used COVID-19 vaccines. Other vaccines include ChAdOx1 nCov-19 (AZD1222, the Oxford-AstraZeneca) and Ad26.COV2.S (Johnson & Johnson/Janssen) is an adenoviral vector-based vaccine. A recombinant human adenovirus type 26 vector encoding the SARS-CoV-2 spike protein is used in the Johnson & Johnson/Janssen vaccination. Conversely, the Oxford-AstraZeneca vaccine is an adenoviral vector that is replication-free and carries a full-length, codon-optimised gene that encodes the SARS-CoV-2 spike protein in chimpanzees. Since none of the three vaccinations contain live viruses, they cannot even trigger viral replication in immunocompromised people [140]. The COVID-19 vaccine should be taken into consideration for patients with hepatocellular carcinoma who are receiving loco regional or systemic therapy without delaying their course of therapy. [141-143]. Similarly, those with chronic liver disease who use antiviral medicines for the treatment of hepatitis B or hepatitis C should not stop taking those medications while getting the COVID-19 vaccination. Hepatopathy has already been linked to the severity of illness brought on by two additional extremely pathogenic coronavirus strains, specifically the MERS-CoV and the (SARS-CoV-1). Many factors affecting the pathogenesis include hypoxic hepatitis (secondary to respiratory failure); hepatic congestion associated with mechanical ventilation (high levels of positive end-expiratory pressure, or PEEP); virally induced intrahepatic cytotoxic T cells and Kupffer cells; and drug toxicity. Hepatic impairment has been linked to the most severe COVID-19 instances when thrombocytopenia, activated coagulation, and fibrinolysis are present [77]. In COVID-19 patients, abnormalities in the liver's biochemistry have been observed. Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) show moderate increases that range from 14 to 53% [12, 77, 120] and are frequently seen in these anomalies. Patients with more severe symptoms than those with mild to moderate symptoms, particularly those who require admission to an intensive care unit (ICU), may have higher rates of transaminase increase [151, 151]. The SARS-CoV-2 gene was the target of PCR testing to diagnose COVID-19 in samples of the nasal or pharynx collected before admission. All patients underwent at least one chest CT scan after admission. These

requirements must be satisfied in order to be released from the hospital: Two negative RT-PCR findings for SARS-CoV-2 respiratory samples obtained at least 24 h apart, remission of respiratory symptoms, improvement in lung inflammation, and normal body temperature for at least three days [152]. Fatty liver was seen in 40.0% of all mild cases [17]. Hepatic dysfunction should be of concern, according to growing research, as it is prevalent in COVID-19 patients [154]. As per meta-analysis, 27.4% of COVID-19 patients had liver dysfunction [155]. As per the WHO report dated March 5, 2021, there have been 115,289,961 COVID-19 cases documented globally. Where the Americas made up the majority (44%), Europe came in second (34%), and Southeast Asia came in third (12%) [8, 156]. Except for individuals under one year old, children with COVID-19 often only have minor symptoms affecting the upper respiratory tract [6]. The most common technique of diagnosis for COVID-19 infection is polymerase chain reaction testing using a nasal swab sample. At the same time, presumptive diagnoses can also be made using clinical, laboratory, and imaging data [8]. Direct invasion and cytokine storms are the two key phases in the pathogenic processes of SARS-CoV-2. Direct invasion is the phase of SARS-CoV-2 infection where the virus penetrates target cells by binding to the angiotensin-converting enzyme 2 (ACE2) receptor through the viral structural spike (S) protein [159]. Pneumocytes, gastrointestinal epithelia, vascular endothelium, the liver, and nasal and bronchial epithelial cells all have the ACE2 receptor [160]. Type 2 Transmembrane serine protease (TMPRSS2) in host target cells promotes viral uptake, particularly in alveolar epithelial type II cells [93]. Some infected individuals may undergo cytokine storms, an extrapulmonary systemic hyperinflammation syndrome [12]. Interleukin (ILs-2, -6, -7, -10) and tumor necrosis factor (TNF) alpha are just a few of the cytokine types that may see an increase in levels as a result of a cytokine storm [162]. A cytokine storm also increases inflammatory biomarkers such as granulocyte colony-stimulating factor, interferon (IFN)-gamma inducible protein 10, and monocyte chemo-attractant protein 1 [163]. Significantly increased cytokine levels are a serious issue since they can lead to serious illness [164]. Serum ferritin, IL-6, and IL-10 were found to be powerful predictors of severe COVID-19 illness by a meta-analysis [23]. The

most prevalent pre-existing liver diseases in COVID-19 patients are cirrhosis, hepatocellular carcinoma (HCC), autoimmune hepatitis, chronic hepatitis B, chronic hepatitis C, metabolically associated fatty liver disease (MAFLD), alcohol-related liver disease (ALD), and autoimmune hepatitis. [21, 67-168]. Certain underlying hepatic conditions may impact the prognosis for COVID-19. It may be the underlying mechanism because MAFLD is a proinflammatoryhypercoagulable condition linked to severe illness and thrombosis in COVID-19 patients [169]. The best course of action for people with end-stage chronic liver disease or immediate liver failure is liver transplantation (LT). [170, 171]. The primary biochemical markers used in the diagnosis of liver damage include (ALT), (AST), total bilirubin (TBIL), (ALP), (GGT), albumin and prothrombin time (PT) [172].

Gastrointestinal damage caused by lung infection

The potential gastric complications have been summarised in Figure 3. Immunity and chronic enteritis depend on CD4+ T cell infiltration of the intestinal mucosa. The entrance of CD4+ T lymphocytes into small intestinal cells is known to be facilitated by the C-C chemical receptor type 9 (CCR9) [173]. CCR9+ CD4+ T lung-derived cells expanded after viral infection, according to Wang *et al* [173]. Chemokine (C-C motif) ligand 25 can be incorporated by the small intestinal epithelium [174], which, therefore, encourages the recruitment of CCR9+ CD4+ T cells into the small intestine [175]. It damages the intestinal flora's balance and the gut immune system. As a result of the high levels of IL-17A produced, T-helper 17 (Th17) cell polarisation and neutrophil recruitment were induced in the gut [176]. As a result, various gastrointestinal symptoms, such as diarrhea and intestinal immunological damage, might manifest. Additionally, intestinal inflammation may cause intestinal flora and cytokines to enter the circulation and travel to the lungs, influencing the immune system [177]. However, there are times when these antiviral immunological processes manage to get beyond the regulatory system, as shown in some patients. It ultimately helps to cause viral infection-induced

multi-organ failure, which includes liver failure. Significant tissue and organ damage can also result from a host immune system's overreaction when stimulated. Significant tissue and organ damage can also result from an overreaction of the host immune system caused by the activation of a systemic inflammatory state brought on by elevated cytokine production. The latter condition, called a "cytokine storm," is recognised to harm tissue significantly [18]. Due to their advanced age and pre-existing medical conditions such as diabetes, asthma, and cardiovascular disease, COVID-19 patients experience more severe consequences, which increases their death rate. Through multisystem inflammation, COVID-19 can harm the liver directly or indirectly. As a result, pre-existing liver illnesses may raise patients' risk of developing severe COVID-19 [179]. The three primary causes of COVID-19-induced liver injury are ischemia and hypoxia. Other considerations include pre-existing liver illness (such as hepatitis steatosis, cholangitis, thrombosis, Kupffer cell proliferation, and liver dysfunction), severe inflammatory responses/sepsis, and the direct cytotoxic action of the virus on cholangiocytes (through ACE2 receptors) [180]. Individuals with severe COVID-19 are at a significant mortality risk for hypoxic liver injury (HLI), which is not an uncommon occurrence. HLI is mainly caused by lung and heart failure and is related to immune-mediated inflammation. Patients with HLI are at a significant risk of death due to numerous organ failures. Comparing HLI instances to non-HLI cases, there is a statistically significant increase in the levels of (TBIL), CRP), procalcitonin and IL-6. Additionally, compared to non-HLI patients, HLI patients had a considerably lower median survival time. [181]. Elevated levels of ferritin, CRP, IL-6, LDH, and cytokine storm (known as cytokine release syndrome) are the hallmarks of this condition [182]. Damage in the liver is triggered by dysfunctional monocytes and macrophages [183]. Hepatotoxicity can be treated successfully with hydroxychloroquine, either alone/or in combination with lopinavir/ritonavir, remdesivir, azithromycin, umifenovir, darunavir, baricitinib, interferon beta and imatinib. These medications are now often used for off-label COVID-19 therapy in several nations due to their quick accessibility [184].

COVID-19 AND LIVER-ASSOCIATED CLINICAL FEATURES

According to reports from China, patients who recuperated from severe COVID-19 symptoms experienced symptoms including pigmentation and a darker complexion. The primary factor for the pigmentation and black face is multiple organ damage, particularly liver disease ^[185, 186]. Through three distinct pathways- liver dysfunctions, aberrant liver function, and liver injury- poor liver function can readily change pigmentation. When the amount of estrogen rises, liver dysfunction prevents the inactivation of estrogen; it reduces the inhibition of thiamine on tyrosinase, which then enhances the transformation of tyrosine into melanin ^[187]. When the liver cannot properly metabolise the melanocyte-stimulating hormone released by the anterior pituitary gland, the body produces more melanin ^[188, 189]. Liver damage increases blood iron levels, and if that blood is given to the facial skin, it may create a darkened face ^[190, 191]. The most prevalent comorbidities experienced by the patients in a clinical review that included 331 critically ill COVID-19 patients were hypertension (136 cases, or 41.1%), CHD (66 cases, or 19.9%), and diabetes (60 cases, or 18.1%). The majority of the patients' treatments included inhaling oxygen (262 cases, or 79.2%), antibacterial therapy (256 cases, or 77.3%), adjuvant corticosteroid therapy (211 cases, or 63.7%), gamma globulin (146 cases, or 44.1%), mechanical ventilation (120 cases, or 36.3%), and muscle relaxants (37 cases, or 11.2%). 273 (82.5%) of the 331 critically ill patients received antiviral medication, including oseltamivir, arbidol, lopinavir/ritonavir, ganciclovir, and interferon. According to an investigation, 36 (13.2%) of the patients in this group experienced liver damage complications ^[192]. This research suggests that lopinavir may make ritonavir more likely to cause liver damage or vice versa. The reactive metabolites and drug-induced oxidative stress were thought to have a role in the molecular mechanism of hydroxychloroquine-induced liver damage, or the inflammatory processes after the viral infection itself may have an ad hoc or synergistic impact ^[193]. Azithromycin, hydroxychloroquine, and lopinavir/ritonavir use were linked to many liver damage pathways, including drug-induced oxidative stress

[194]. Due to the many medications involved, providing a consistent molecular idea suited for all the pharmaceuticals under consideration is impractical. However, the molecular mechanisms through which a single medication, such as acetaminophen, damages the liver through CYP, particularly its isoform 2E1, are well understood and may be applied to individuals who take an excessive amount of the drug.

Contrary to the majority of other medicines that generate unanticipated idiosyncratic liver disease, acetaminophen's intrinsic liver harm is predictable. Polypharmacy, a well-documented therapeutic strategy employed for COVID-19 patients (for instance, patients who were treated with up to 18 different medicines), poses a more significant risk for DILI than the use of a single drug from a molecular perspective. If two or more hepatotoxic medicines were administered concurrently for therapy, polypharmacy increased the incidence of DILI by a ratio of up to six [195]. SARS-CoV-2 can cause an asymptomatic infection or a condition that might be fatal [201,202]. Since the COVID-19 pandemic began in 2019, there have been worries that people with pre-existing chronic liver disease (CLD) may be more likely to experience worse health outcomes after contracting SARS-CoV-2. This is particularly significant considering that advanced age, obesity, diabetes, and severe COVID-19 and CLD share risk factors [70, 203]. Progressively rising levels of ALT, AST, ALP, and LDH were found during hospitalisation in the first case of COVID-19 reported in the United States.

In contrast, the bilirubin level with prothrombin time remained normal [63]. Males are more likely than females to experience liver impairment, according to Xie *et al*'s analysis of liver function in patients not receiving critical care [47]. Fifty-two patients from the COVID-19 trial who required mechanical breathing or help with at least 60% of the inspired oxygen fraction were included in the research. According to the research, 29% of the patients had liver damage, 15% had acute renal damage, and another 15% had cardiac damage [203]. The liver damage caused by COVID-19 is hepatocellular rather than Cholestatic, and as a result, it primarily manifests as increases in ALT, AST, and LDH levels. Hepatocellular damage markers like AST are also linked with mortality risk in COVID-19 patients [204].

HEMATOLOGICAL AND HEPATIC VARIATIONS

Changes in Blood cellularity are observed during the early onset of the disease. A study with 1099 participants showed that 83.2 per cent, 36.2 per cent, and 33.7 per cent of the patients had lymphopenia, thrombocytopenia, and leukopenia, respectively. These patients showed a rise in ALT and AST values, which indicated liver damage, particularly in severe COVID-19 cases [3, 59,62, 205]. It is speculated that the virus's attachment to ACE2 can directly cause cytopathic damage, which can lead to liver damage. Patients with COVID-19 also have cholangiocytes with high ACE2 expression. In addition to an extended prothrombin time, hypoproteinemia and coagulation abnormalities are further COVID-19 hepatic symptoms. This phenomenon may even be secondary to the use of hepatotoxic medicines as the cause of acute viral hepatitis, which is thought to be the source of viral tropism in the liver tissue [201-206]. In disseminated intravascular coagulation (DIC) conditions, an increase in the D dimer and thrombocytopenia was observed in 36.2%–46.4% of the critically ill patients, and a poorer prognosis was identified [200, 201].

THERAPEUTIC RECOMMENDATIONS FOR COVID-19: VACCINES, LABEL AND OFF-LABEL MEDICATIONS FOR PATIENT CARE

Classical antimalarial drugs include chloroquine, aminoquinolines, and hydroxychloroquine, which are polymerase inhibitors. The drug kills the malaria parasite by accelerating the formation of poisonous heme within the parasite through heme polymerase inhibition. It is believed that the medicines' function in treating COVID-19 is to stop the virus from entering host cells by limiting the glycosylation of host receptors and by inhibiting the generation of viral proteins through endosomal acidification. The WHO recommended the use of hydroxychloroquine or chloroquine together with lopinavir/ritonavir for COVID-19 therapy, regardless of the severity and length of the disease. On the other hand, regardless of the severity of the disease, remdesivir and systemic corticosteroids are suggested as prospective pharmacological

options for conditional use in routine care of hospitalised COVID-19 patients (WHO/2019-nCoV/therapeutics/2020.1). The WHO recognises this type of off-label pharmaceutical usage as being nation-specific. In several nations, clinicians provide COVID-19 therapeutic options that have yet to receive official approval (MEURI; <http://www.who.int/>). COVID-infected patients have been treated with off-label, compassionate-use treatments such as interferon and the repurposed medication Kaletra, which is an authorised combination of the virus, steroids, anti-IL-6 inhibitors, protease inhibitors lopinavir and ritonavir, chloroquine, and azithromycin [196].

Coronaviruses are positive-sense ssRNA viruses with an envelope measuring 80–220 nm in diameter. The virus is known as a coronavirus because it has an envelopemeasuring 20 nm-long spikes that resemble the sun's corona when seen under an electron microscope. Both humans and animals can become ill as a result of the infection. Among the RNA viruses that are currently known, it has the largest genome [197]. The coronavirus nucleoprotein (N) covers the RNA genome to create a coiled tubular shape. The viral envelope (E) that surrounds this helical nucleocapsid contains two or three structural proteins, including the spike structural protein (S), which serves as the target for neutralising antibodies, and the matrix protein (M), which is incorporated in the envelope. Numerous beta-coronavirus strains also include hemagglutinin esterase. There are four structural proteins viz. N, E, M, and S and RNA-dependent RNA polymerase (RdRp), which are encoded by the five essential genes in coronaviruses. The highly conserved arrangement of these genes is 5'-RdRp-S-E-M-N-3' [198].

It was observed that 51.1% of all confirmed cases were males. 80% of the confirmed cases that were reported either had either no pneumonia or mild to moderate. In comparison, 15% showed severe pneumonia, and 6% required critical care owing to respiratory failure, shock, and multiple organ failure. The COVID-19 fatality rate is 3.8% across all of China, with fatality rates of 5.8% in Wuhan City and 0.7% across the remainder of mainland China. Old age (60 years and above) and medical comorbidities, viz. hypertension, diabetes mellitus, cardiovascular disease, chronic pulmonary illness,

or cancer, are risk factors for acquiring severe pneumonia or dying from it. Laboratory testing found leukopenia, lymphopenia, and mildly raised C-reactive protein in COVID-19 cases, but patients having severe pneumonia showed higher levels of leukocytes, neutrophils, and creatinine kinase. According to computed tomography of the chest, both lung fields exhibit a ground glass appearance, interstitial infiltration, or numerous patchy consolidations [199]. Some individuals had the rapid onset of severe pneumonia, pulmonary oedema, acute respiratory distress syndrome, acute respiratory failure, and multiple organ failure. Chen *et al* [200] were the first to detect abnormal liver enzymes in infected patients. Forty-three cases (43.4%) of Wuhan's confirmed patients had elevated blood levels of the enzymes aspartate aminotransferase (AST), alanine aminotransferase (ALT), and lactic dehydrogenase. Except for one instance, which had extremely high levels of aminotransferases, most had a modest increase in aminotransferase. None, however, was seen to have liver failure or apparent intrahepatic cholestasis [200]. The biggest subfamily of spike viruses in the Nidovirales family is the coronaviruses (CoV). In the past 20 years, the virus has been responsible for three major outbreaks, including the most recent pandemic that the SARS-CoV-1 brought on. In 2002, Guangdong Province in China had the first outbreak of the twenty-first century. SARS-CoV-1 formed a severe form of SARS and caused 8098 fatalities (9.6%) worldwide [209, 210]. The lung is the main organ affected by pneumonia caused by COVID-19. Typical respiratory symptoms, including dyspnea, coughing up sputum, exhaustion, ARDS, respiratory failure, and even death, affect the majority of COVID-19 patients. Contrarily, extrapulmonary clinical manifestations can affect a variety of other organs, including the cardiovascular system (viz; acute coronary syndrome, arrhythmias, pericarditis, myocarditis,) the kidneys (acute kidney injury and acute tubular necrosis) and the liver [211].

ABNORMALITIES IN LIVER FUNCTION TEST PREVALENCE AMONG COVID-19 PATIENTS

There are few studies particularly investigating the clinical characteristics of liver failure in COVID-19 patients. These investigations revealed a rising trend in the liver enzyme levels seen in individuals who were severely ill or who did not survive. The percentage of patients having elevated ALT, AST, and GGT levels was 82%, 75%, and 72%, respectively. According to a recent finding, the incidence of abnormal liver test results was 76.3%, and that of liver damage was 21.5% among hospitalised COVID-19 patients^[212]. In that research, 26.7% of the patients with abnormal liver tests indicated a tendency toward developing severe pneumonia within two weeks of hospitalisation, and individuals had higher levels of abnormal liver tests. Patients diagnosed with severe COVID-19 had considerably more liver damage than those with non-severe COVID-19. The scientists also noted that individuals with hepatocyte types had noticeably increased chances of suffering from severe COVID-19. In a different investigation, the levels of ALT, AST, GGT, ALP, and TB were significantly greater in dead patients than in healthy ones^[202].

POSSIBLE IMPACT OF DRUGS ON LIVER FUNCTION IN COVID-19 PATIENTS

Additionally, it is hypothesised that COVID-19 individuals who use certain medications may suffer from liver damage. For instance, individuals with COVID-19 may have liver damage as a result of taking various medications, including antibiotics, antivirals, and antipyretics, as well as analgesics and traditional Chinese medicine^[203]. It was observed that medications like ACE inhibitors and angiotensin II receptor blockers may impair liver functioning in COVID-19 patients. In research, participants who used ACEIs or ARBs throughout their hospitalisation had higher liver enzyme levels; however, the rise was not statistically significant in those who were not hospitalised^[213]. Serum GGT, a possible cholangiocyte damage diagnostic marker, is up to 72% higher in individuals with severe COVID-19^[202,209]. According to a preliminary investigation, the ACE2

receptor is highly expressed in cholangiocytes^[213]. This data suggests that SARS-CoV-2 may bind to cholangiocytes that are ACE2-positive and cause liver damage^[212]. Nevertheless, liver tissue from a patient who passed away from COVID-19 did not contain any viral inclusions^[214]. A significant factor in the liver damage brought on by COVID-19 may be dysfunctional control of the innate immune response. The following potential processes could cause COVID-19 patients' livers to become damaged: (i) immune-mediated inflammation, including cytokine storm and hypoxia caused by pneumonia; (ii) Direct cytotoxicity due to active viral replication in the liver cells; (iii) Drug-induced liver damage, including the potential hepatotoxicity of uminefovir in patients with severe COVID-19, concerning antiviral medications like lopinavir/ritonavir, chloroquine as remdesivir, and tocilizumab; (iv) Patients who have a history of chronic hepatic illness are more susceptible to acquiring hepatic damage from this viral infection; (v) Reactivation of pre-existing hepatic disease Hepatitis B virus reactivation could occur as a result of using biological medications such as tocilizumab and baricitinib, which have the potential to cause liver impairment. Another unanswered question is whether SARS-CoV-2 infection worsens cholestasis in an individual or with underlying cholestatic hepatic disorders. More mechanistic research is needed to understand better how viruses enter and replicate in liver cells and the possible liver effects of the prescriptions used to treat COVID-19^[212].

MANAGEMENT AND PREVENTION

Preventing liver damage in COVID-19

All COVID-19 patients should have their liver biochemical markers monitored, including ALT/AST, albumin, bilirubin, and prothrombin time, for possible risk of liver damage. For instance, if the serum AST and LDH levels increase while the ALT level is normal, skeletal muscle or myocardial damage should be diagnosed rather than a liver

injury because chronic liver illness is a significant medical burden among older COVID-19 patients; doctors are encouraged to give attention to the treatment of pre-existing liver disease. Antiviral medications for the treatment of chronic hepatitis B should not be stopped to prevent the virus from reactivating. However, anti-HBV medicines should also be considered for patients receiving glucocorticoid therapy [12, 13, 18, 196]. Those receiving glucocorticoids or immunosuppressants as part of their treatment for autoimmune liver disease should be closely monitored because of their compromised immune systems. People with cirrhosis also require close monitoring for the development of complications and secondary infections [15,18]. Due to the new coronavirus's ability to trigger a cytokine storm and a sequence of immunological responses, certain COVID-19 patients may quickly advance to multiple organ failure or death, septic shock, and acute respiratory distress syndrome. Therefore, prompt treatment in severe instances is necessary to avoid any additional liver damage. During COVID-19 clinical management, a variety of antiviral drugs, nonsteroidal anti-inflammatory drugs (NSAIDs), traditional Chinese herbs and glucocorticoids may be used. As such, it is advisable to streamline treatment and minimise the use of redundant medication types, doses, and durations to lower the risk of drug-induced liver injury [215].

COVID-19 Liver injury management

The primary COVID-19 treatments currently employed include intensive care, treating hypoxemia with oxygenation assistance/mechanical ventilation, providing continuous renal replacement therapy for cytokine storm syndrome, maintaining sufficient blood volume, and other supportive therapies (Table 1). These therapies are essential for preventing and treating multiple organ failures, including liver damage [216].

RESULTS AND DIRECTIONS FOR THE FUTURE

The COVID-19 pandemic has caused considerable setbacks in several healthcare services, particularly the management of CLD, and has been a historically severe worldwide health disaster. According to Besur *et al* [208], the pandemic delayed CLD

screening and frequent follow-up appointments, which had an impact on CLD prevention and treatment¹ and worsened the prognosis for CLD patients. Late detection of CLD consequences such as hepatocellular carcinoma (HCC) may have an impact on these patient's clinical outcomes. Social isolation practices have increased the likelihood that CLD patients may have decompensation, mental health impairment, and malnutrition^[210]. Additionally, individuals with COVID-19 reported experiencing recurrent gastrointestinal issues^[77]. In individuals with severe COVID-19, research found an abnormally high level of aminotransferase that may not have a hepatic origin^[79]. The study shows a consistent link between the severity of COVID-19 and liver damage, although the mechanisms behind this damage are still unknown, given the multifaceted nature of the condition. One possible condition is hepatocyte apoptosis^[211]. It was noted that while Frank's steatohepatitis symptoms were only present in two instances, macrovesicular steatosis, which displays a fat distribution unusual for NAFLD, was widespread in patients (75%). COVID-19 may have exacerbated the steatosis in some individuals. This discovery is in line with those made public by previous investigations. For instance, a team connected to the Centers for Disease Control revealed that 50% of the livers from autopsies under study had steatosis^[212]. ACE2 and TMPRSS2 are primarily used by SARS-CoV-2 as the docking and entrance receptor on host cells for cellular entry^[213]. Additionally, it has been proposed that myositis, rather than liver damage, maybe the cause of the high aminotransferase level in COVID-19 individuals^[215]. A reliable predictor of death was hypoalbuminemia^[216]. Even at therapeutic quantities, acetaminophen, a common medication used to treat COVID-19 symptoms, can affect aminotransferase levels^[217]. Compared to individuals without NAFLD, patients with NAFLD showed quicker disease development and a longer viral shedding time^[218]. Obese patients with NAFLD also showed an increased risk for severe disease^[219]. High positive end-respiratory pressure (PEEP) may cause comparable hemodynamic changes in the liver of mechanically ventilated patients^[200, 211]. Most reports and research concentrate largely on the causes and side effects of cardiovascular damage due to the Kawasaki-like presentation of MIS-C^[212, 203].

Recently, the assessment of COVID-19 severity or MIS-C presentation has incorporated liver involvement and the use of liver enzymes as potential prognostic markers [204]. Adults who have comorbid conditions, including obesity, diabetes, or hypertension, may develop non-alcoholic hepatosteatosis (fatty liver disease). The condition worsens the patients' SARS-CoV-2 infection [205]. According to research published in September 2020 by Zhou *et al*, younger children were more commonly affected by liver involvement in COVID-19 instances than older children. Young age-related liver immaturity is thought to be the cause [206]. Acute COVID-19 cases were thought to be caused by direct liver damage from hepatotropic viral invasion because of the reported ACE2 receptors on the surface of liver and bile duct epithelial cells [207]. In contrast, MIS-C [208] has a precise immune-mediated hepatotoxicity mechanism. When the COVID-19 infection is severe, "cytokine storm" and multi-organ dysfunction are shown as types of liver involvement where cytokines encourage the increase and release of liver enzymes [209]. The progression of the reported situation is comparable to sepsis-associated liver dysfunction, in which increased levels of hepatic markers and bilirubin, as well as reduced synthesis function, result in hypoproteinemia and coagulation abnormalities [219]. Additionally, as part of the cytokine storm, IL-6 participation in COVID-19-related liver failure has been demonstrated [200]. The subfamily of SARS-CoV-2 has four genera, namely Alpha-coronavirus, Beta-coronavirus, Gamma-coronavirus, and Delta-coronavirus, according to genomic and phylogenetic studies [201]. Early in December 2019, Wuhan, China, reported the first case of pneumonia with a previously unidentified origin after being identified as a new beta-coronavirus using high-throughput sequencing research; the case was given the designation SARS-CoV-2. The WHO formally proclaimed the SARS-CoV-2 virus a pandemic of worldwide concern following its sudden global outbreak [172]. Early liver impairment in COVID-19 individuals raises their mortality risk. Cholestasis was detected in 151 patients (42.5%) and hepatocellular damage in 101 patients (28.5%). It was shown that severely sick individuals were more likely to have liver dysfunction [173]. 9.6% of the chosen group had an elevated ALP level of > 150 U/L and a cholestatic pattern of liver damage. High

4

levels of ALT/AST, gamma-glutamyl transferase (GGT), ALP, and total bilirubin were found to be the aberrant liver functions that were observed in a different investigation of cholestatic liver damage carried out at the Shanghai Public Health Clinical Center from January 20 to December 31, 2020 [174]. The most frequent cancer is hepatocellular carcinoma (HCC), nevertheless. Patients with HCC also have underlying CLD, such as chronic hepatitis B or C virus infection, NAFLD and alcoholic liver damage [175]. According to reports, COVID-19 infections are very likely to occur in cancer patients. A study in a Chinese hospital showed that 28 out of 1276 confirmed COVID-19 cases had cancers, with two having HCC [176]. SARS-CoV-2 infection of liver cells may be directly connected to liver dysfunction in COVID-19 patients. About 2% to 10% of COVID-19 patients who had diarrhea contain SARS-CoV-2 RNA in their blood and stool, suggesting the possibility of exposure to the liver virus. The upper respiratory tract, lung tissue, and liver cholangiocytes are considered the main target sites for SARS-CoV-2 and SARS-CoV due to their affinity for the ACE2 receptor. In these tissues, the virus multiplies and shows symptoms [207] and the reported conspicuous cytopathy. Disturbed levels of liver enzymes, an elevated alveolar-arterial oxygen gradient and GGT level, a reduced level of albumin, and the presence of circulating CD4+ T cells and B lymphocytes are all indicators of SARS-CoV-2 infection and significant apoptosis with binuclear hepatocytes are the main histological characteristics of COVID-19 Liver infection [219].

CONCLUSION

COVID-19 has been shown to impact additional organs in addition to the respiratory system, with the liver being one of the most often afflicted organs. Several factors, such as virus-associated immunological liver injury, direct cholangiocyte destruction resulting in liver injury, hypoxia injury, drug-induced liver injury, and autoimmune liver disease, can result in liver damage.
